## ABSTRACT

The high mapping resolution of multiparental populations, combined with technology to measure tens of thousands of phenotypes, presents an opportunity for quantitative methods to enhance understanding of the genetic architecture of complex traits. When multiple traits map to a common genomic region, knowledge of the number of distinct loci provides important insight into the underlying mechanism and can assist planning for subsequent experiments. We extend the work of [Jiang and Zeng \(1995\)](#) to develop a likelihood ratio test, for a pair of traits, of the null hypothesis of pleiotropy against the alternative hypothesis of separate QTL, for the case of more than two alleles. We also incorporate polygenic random effects to account for variable relatedness among subjects. We use a parametric bootstrap to determine statistical significance. We apply our methods to a behavioral genetics data set from Diversity Outbred mice, where we find evidence for presence of two distinct loci in a 2.5 cM region. Our methods have been incorporated into the R package `qt12pleio`.

**KEYWORDS** Quantitative trait locus; pleiotropy; multivariate analysis; linear mixed effects models; systems genetics; ...

Complex trait studies in multiparental populations present new challenges in statistical methods and data analysis. Among these is the development of strategies for multivariate trait analysis. The joint analysis of two or more traits allows one to address additional questions, such as whether two traits share a single pleiotropic locus.

Previous research addressed the question of pleiotropy vs. separate QTL in two-parent crosses. [Jiang and Zeng \(1995\)](#) developed a likelihood ratio test for pleiotropy vs. separate QTL for a pair of traits. Their approach assumed that each trait was affected by a single QTL. Under the null hypothesis, the two traits were affected by a common QTL, and under the alternative hypothesis the two traits were affected by distinct QTL. [Knott and Haley \(2000\)](#) used linear regression to develop a fast approximation to the test of [Jiang and Zeng \(1995\)](#), while [Tian \*et al.\* \(2016\)](#) used the methods from [Knott and Haley \(2000\)](#) to dissect QTL hotspots in a  $F_2$  population.

Multiparental populations, such as the Diversity Outbred (DO) mouse population ([Churchill \*et al.\* 2012](#)), enable high-precision mapping of complex traits ([de Koning and McIntyre 2014](#)). The DO mouse population began with progenitors of the Collaborative Cross (CC) mice ([Churchill \*et al.\* 2004](#)). Each DO mouse is a highly heterozygous genetic mosaic of alleles from the eight CC founder lines. Random matings among non-siblings have maintained the DO population for more than 23 generations ([Chesler \*et al.\* 2016](#)).

Several limitations of previous pleiotropy vs. separate QTL tests prevent their direct application in multiparental populations. First, multiparental populations can have complex patterns of relatedness among subjects, and failure to account for these patterns of relatedness may lead to spurious

results (Yang *et al.* 2014). Second, previous tests allowed for only two founder lines (Jiang and Zeng 1995). Finally, Jiang and Zeng (1995) assumed that the null distribution of the test statistic follows a chi-square distribution.

We developed a pleiotropy vs. separate QTL test for two traits in multiparental populations. Our test builds on research that Jiang and Zeng (1995), Knott and Haley (2000), Tian *et al.* (2016), and Zhou and Stephens (2014) initiated. Our innovations include the accommodation of  $k$  founder alleles per locus (compared to the traditional two founder alleles per locus) and the incorporation of multivariate polygenic random effects to account for relatedness. Furthermore, we implemented a parametric bootstrap to calibrate test statistic values (Efron 1979; Tian *et al.* 2016).

Below, we describe our likelihood ratio test for pleiotropy vs. separate QTL. In simulation studies, we find that it is slightly conservative, and that it has power to detect two separate loci when the univariate LOD peaks are strong. We further illustrate our approach with an application to data on a pair of behavior traits in a population of 261 DO mice (Logan *et al.* 2013; Recla *et al.* 2014). We find modest evidence for distinct QTL in a 2.5-cM region on mouse chromosome 8.

## Methods

Our strategy involves first identifying two traits that map to a common genomic region. We then perform a two-dimensional, two-QTL scan over the genomic region, with each trait affected by one QTL of varying position. We identify the QTL position that maximizes the likelihood under pleiotropy (that is, along the diagonal where the two QTL are at a common location), and the ordered pair of positions that maximizes the likelihood under the model where the two QTL are allowed to be distinct. The logarithm of the ratio of the two likelihoods is our test statistic. We calibrate this test statistic with a parametric bootstrap.

### Data structures

The data consist of three objects. The first is an  $n$  by  $k$  by  $m$  array of allele probabilities for  $n$  subjects with  $k$  alleles and  $m$  marker positions on a single chromosome [derived from the observed SNP genotype data by a hidden Markov model; see Broman *et al.* (2019)]. The second object is an  $n$  by 2 matrix of phenotype values. Each column is a phenotype and each row is a subject. The third object is an  $n$  by  $c$  matrix of covariates, where each row is a subject and each column is a covariate.

One additional object is the genotype-derived kinship matrix, which is used in the linear mixed model to account for population structure. We are focusing on a defined genomic interval, and we prefer to use a kinship matrix derived by the “leave one chromosome out” (LOCO) method (Yang *et al.* 2014), in which the kinship matrix is derived from the genotypes for all chromosomes except the chromosome under test.

### Statistical Models

Focusing on a pair of traits and a particular genomic region of interest, the next step is a two-dimensional, two-QTL scan (Jiang and Zeng 1995). We consider two QTL with each affecting a different trait, and consider all possible pairs of locations for the two QTL. For each pair of positions, we fit the multivariate linear mixed effects model defined in Equation 1. Note that we have assumed an additive genetic model throughout our analyses, but extensions to design matrices that include dominance are straightforward.

$$\text{vec}(Y) = X\text{vec}(B) + \text{vec}(G) + \text{vec}(E) \quad (1)$$

where  $Y$  is the  $n$  by 2 matrix of phenotypes values;  $X$  is a  $2n$  by  $2(k + c)$  matrix that contains the  $k$  allele probabilities for the two QTL positions and the  $c$  covariates in diagonal blocks;  $B$  is a  $(k + c)$  by 2 matrix of allele effects and covariate effects;  $G$  is a  $n$  by 2 matrix of random effects; and  $E$  is a  $n$  by 2 matrix of random errors.  $n$  is the number of mice. The ‘vec’ operator stacks columns from a matrix into a single vector. For example, a 2 by 2 matrix inputted to ‘vec’ results in a vector with length 4. Its first two entries are the matrix’s first column, while the third and fourth entries are the matrix’s second column.

We also impose distributional assumptions on  $G$  and  $E$ :

$$G \sim MN_{nx2}(0, K, V_g) \quad (2)$$

and

$$E \sim MN_{nx2}(0, I, V_e) \quad (3)$$

where  $MN_{nx2}(0, V_r, V_c)$  denotes the matrix-variate ( $n$  by 2) normal distribution with mean being the  $n$  by 2 matrix with all zero entries and row covariance  $V_r$  and column covariance  $V_c$ . We assume that  $G$  and  $E$  are independent.

#### **Parameter inference and log likelihood calculation**

Inference for parameters in multivariate linear mixed effects models is notoriously difficult and can be computationally intense (Meyer 1989, 1991). Thus, we estimate  $V_g$  and  $V_e$  under the null hypothesis of no QTL, and then taken them as fixed and known in our two-dimensional, two-QTL genome scan. We use restricted maximum likelihood methods to fit the model:

$$vec(Y) = X_0 vec(B) + vec(G) + vec(E) \quad (4)$$

where  $X_0$  is a  $2n$  by  $2(c + 1)$  matrix whose first column of each diagonal block  $X_0$  has all entries equal to one (for an intercept); the remaining columns are the covariates.

We draw on our R implementation (Boehm 2018) of the GEMMA algorithm for fitting a multivariate linear mixed effects model with expectation-maximization (Zhou and Stephens 2014). We use restricted maximum likelihood fits for the variance components  $V_g$  and  $V_e$  in subsequent calculations of the generalized least squares solution  $\hat{B}$ .

$$\hat{B} = (X^T \hat{\Sigma}^{-1} X)^{-1} X^T \hat{\Sigma}^{-1} vec(Y) \quad (5)$$

where

$$\hat{\Sigma} = \hat{V}_g \otimes K + \hat{V}_e \otimes I_n \quad (6)$$

where  $\otimes$  denotes the Kronecker product,  $K$  is the kinship matrix, and  $I_n$  is a  $n$  by  $n$  identity matrix. We then calculate the log likelihood for a normal distribution with mean  $X vec(\hat{B})$  and covariance  $\hat{\Sigma}$  that depends on our estimates of  $V_g$  and  $V_e$  (Equation 6).

#### **Pleiotropy vs. separate QTL hypothesis testing framework**

Our test applies to two traits considered simultaneously. Below,  $\lambda_1$  and  $\lambda_2$  denote putative locus positions for traits one and two. We quantitatively state the competing hypotheses for our test as:

$$\begin{aligned} H_0 : \lambda_1 &= \lambda_2 \\ H_A : \lambda_1 &\neq \lambda_2 \end{aligned} \quad (7)$$

112 Our likelihood ratio test statistic is:

$$\text{LOD} = \log_{10} \left[ \frac{\max_{\lambda_1, \lambda_2} L(B, \Sigma, \lambda_1, \lambda_2)}{\max_{\lambda} L(B, \Sigma, \lambda, \lambda)} \right] \quad (8)$$

113 where  $L$  is the likelihood for fixed QTL positions, maximized over all other parameters.

### 114 **Visualizing profile LOD traces**

115 The output of the above analysis is a two-dimensional  $\log_{10}$  likelihood surface. To visualize these  
116 results, we followed an innovation of Zeng *et al.* (2000) and Tian *et al.* (2016), and plot three traces:  
117 the results along the diagonal (corresponding to the null hypothesis of pleiotropy), and then the  
118 profiles derived by fixing one QTL's position and maximizing over the other QTL's position.

119 We define the LOD score for our test:

$$\text{LOD}(\lambda_1, \lambda_2) = ll_{10}(\lambda_1, \lambda_2) - \max ll_{10}(\lambda, \lambda) \quad (9)$$

120 where  $ll_{10}$  denotes  $\log_{10}$  likelihood.

121 We follow Zeng *et al.* (2000) and Tian *et al.* (2016) in defining profile LOD by the equation

$$\text{profile LOD}_1(\lambda_1) = \max_{\lambda_2} \text{LOD}(\lambda_1, \lambda_2) \quad (10)$$

122 We define profile  $\text{LOD}_2(\lambda_2)$  analogously. The maximum value for the profile  $\text{LOD}_1$  profile  $\text{LOD}_2$   
123 traces the same and are non-negative, and give the overall LOD test statistic.

124 We construct the pleiotropy trace by calculating the log-likelihoods for the pleiotropic models at  
125 every position.

$$\text{LOD}_p(\lambda) = ll_{10}(\lambda, \lambda) - \max ll_{10}(\lambda, \lambda) \quad (11)$$

126 By definition, the maximum value for this pleiotropy trace is zero.

### 127 **Bootstrap for test statistic calibration**

128 We use a parametric bootstrap to calibrate our test statistic (Efron 1979). While Jiang and Zeng (1995)  
129 used quantiles of a chi-squared distribution to determine p-values, this does not account for the two-  
130 dimensional search over QTL positions. We follow the approach of Tian *et al.* (2016), and identify  
131 the maximum likelihood estimate of the QTL position under the null hypothesis of pleiotropy. We  
132 then use the inferred model parameters under that model and with the QTL at that position to  
133 simulate bootstrap data sets according to the model in equations 1–3. For each of  $b$  bootstrap data  
134 sets, we perform a two-dimensional QTL scan (over the genomic region of interest) and derive the  
135 test statistic value. We treat these  $b$  test statistics as the empirical null distribution, and calculate  
136 a p-value as the proportion of the  $b$  bootstrap test statistics that equal or exceed the observed one,  
137 with the original data,  $p = \#\{i : \text{LOD}_i^* \geq \text{LOD}\} / b$  where  $\text{LOD}_i^*$  denotes the LOD score for the  $i$ th  
138 bootstrap replicate and LOD is the observed test statistic.

### 139 **Data & Software Availability**

140 Our methods have been implemented in an R package, qt12pleio, available at GitHub:

141 <https://github.com/fboehm/qt12pleio>

142 Custom R code for our analyses and simulations are at GitHub:

143 <https://github.com/fboehm/qt2pleio-manuscript>

144 The data from Recla *et al.* (2014) and Logan *et al.* (2013) are available at the Mouse Phenome Database:

**Table 1** Type I error rates for all runs in our  $2^3$  experimental design. We set (marginal) genetic variances (*i.e.*, diagonal elements of  $V_g$ ) to 1 in all runs.  $V_e$  was set to the 2 by 2 identity matrix in all runs. We used allele probabilities at a single genetic marker to simulate traits for all eight sets of parameter inputs. In the column “Allele effects partitioning”, “ABCD:EFGH” means that lines A–D carry one QTL allele while lines E–H carry the other allele. “F:ABCDEGH” means the QTL has a private allele in strain F.

Run	$\Delta(\text{Allele effects})$	Allele effects partitioning	Genetic correlation	Type I error rate
1	6	ABCD:EFGH	0	0.032
2	6	ABCD:EFGH	0.6	0.035
3	6	F:ABCDEGH	0	0.040
4	6	F:ABCDEGH	0.6	0.045
5	12	ABCD:EFGH	0	0.038
6	12	ABCD:EFGH	0.6	0.042
7	12	F:ABCDEGH	0	0.025
8	12	F:ABCDEGH	0.6	0.025

145 <https://phenome.jax.org/projects/Chesler4> and <https://phenome.jax.org/projects/Recla1>.  
146 They are also available in R/qtl2 format at <https://github.com/rqtl/qtl2data>.

## 147 Simulation studies

148 We performed two types of simulation studies, one for type I error rate assessment and one to  
149 characterize the power to detect separate QTL. To simulate traits, we specified  $X$ ,  $B$ ,  $V_g$ ,  $K$ , and  $V_e$   
150 matrices (Equations 1–3). For both we used the allele probabilities from a single genomic region  
151 derived empirically from data for a set of 479 Diversity Outbred mice from Keller *et al.* (2018).

### 152 Type I error rate analysis

153 To quantify type I error rate (*i.e.*, false positive rate), we simulated 400 pairs of traits for each of eight  
154 sets of parameter inputs (Table 1). We used a  $2^3$  factorial experimental design with three factors:  
155 allele effects difference, allele effects partitioning, and genetic correlation, *i.e.*, the off-diagonal entry  
156 in the 2 by 2 matrix  $V_g$ .

157 We chose two strong allele effects difference values, 6 and 12. These ensured that the univariate  
158 phenotypes mapped with high LOD scores to the region of interest. For the allele partitioning factor,  
159 we used either equally frequent QTL alleles, or a private allele in the CAST strain (F). For the residual  
160 genetic correlation (the off-diagonal entry in  $V_g$ ), we considered the values 0 and 0.6. The marginal  
161 genetic variances (*i.e.*, the diagonal entries in  $V_g$ ) for each trait were always set to one.

162 We performed 400 simulation replicates per set of parameter inputs, and each used  $b = 400$   
163 bootstrap samples. For each bootstrap sample, we calculated the test statistic (Equation 8). We  
164 then compared the test statistic from the simulated trait against the empirical distribution of its 400  
165 bootstrap test statistics. When the simulated trait’s test statistic exceeded the 0.95 quantile of the  
166 empirical distribution of bootstrap test statistics, we rejected the null hypothesis. We observed that

**Figure 1** Pleiotropy vs. separate QTL power curves for each of four sets of parameter settings. Factors that differ among the four curves are allele effects difference and allele partitioning. Olive green denotes high allele effects difference and allele partitioning into two groups of four. Purple denotes high (2) allele effects difference with unequal allele partitioning. Red and blue both have the low allele effects difference with even and uneven allele partitioning, respectively.

the test is slightly conservative over our range of parameter selections (Table 1), with estimated type I error rates  $< 0.05$ .

### Power analysis

We also investigated the power to detect the presence of two distinct QTL. We used a  $2 \times 2 \times 5$  experimental design, where our three factors were allele effects difference, allele effects partitioning, and inter-locus distance. The two levels of allele effects difference were 1 and 2. The two levels of allele effects partitioning were as in the type I error rate studies, ABCD:EFGH and F:ABCDEGH (Table S1). The five levels of interlocus distance were 0, 0.5, 1, 2, and 3 cM.  $V_g$  and  $V_e$  were both set to the 2 by 2 identity matrix in all power study simulations.

We simulated 400 pairs of traits per set of parameter inputs. For each simulation replicate, we calculated the likelihood ratio test statistic. We then applied our parametric bootstrap to calibrate the test statistics. For each simulation replicate, we used  $b = 400$  bootstrap samples. Because the bootstrap test statistics within a single set of parameter inputs followed approximately the same distribution, we pooled the  $400 \times 400 = 160,000$  bootstrap samples per set of parameter inputs and compared each test statistic to the empirical distribution derived from the 160,000 bootstrap samples. However, for parameter inputs with interlocus distance equal to zero, we didn't pool the 160,000 bootstrap samples; instead, we proceeded by calculating power (*i.e.*, type I error rate, in this case), as we did in the type I error rate study above.

We present our power study results in Figure 1. Power increases as interlocus distance increases. The top two curves correspond to the case where the QTL effects are largest. For each value for the

QTL effect, power is greater when the QTL alleles are equally frequent, and smaller when a QTL allele is private to one strain. One can have high power to detect that the two traits have distinct QTL when they are separated by  $> 1$  cM and when the QTL have large effect.

## Application

To illustrate our methods, we applied our test to data from [Logan et al. \(2013\)](#) and [Recla et al. \(2014\)](#), on 261 DO mice measured for a set of behavioral phenotypes. [Recla et al. \(2014\)](#) identified *Hydin* as the gene that underlies a QTL on chr 8 at 57 cM for the “hot plate latency” phenotype (a measure of pain tolerance). The phenotype “percent time in light” in a light-dark box (a measure of anxiety) was measured on the same set of mice ([Logan et al. 2013](#)) and also shows a QTL near this location, which led us to ask whether *Hydin* affects both traits. The two traits show a correlation of  $-0.15$  (Figure S1).

QTL analysis with the LOCO method, and using sex as an additive covariate, showed multiple suggestive QTL for each phenotypes (Figures S2 and S3; Table S2). For our investigation of pleiotropy, we focused on the interval 53–64 cM on chromosome 8. The univariate QTL results for this region are shown in Figure 2.

The estimated QTL allele effects for the two traits are quite different (Figure 3). With the QTL placed at 55 cM, for “percent time in light”, the WSB and PWK alleles are associated with large phenotypes and NOD with low phenotypes. For “hot plate latency”, on the other hand, CAST and NZO show low phenotypes and NOD and PWK are near the center.

In applying our test for pleiotropy, we performed a two-dimensional, two-QTL scan for the pair of phenotypes. With these results, we created a profile LOD plot (Figure 4). The profile LOD for “percent time in light” (in brown) peaks near 55 cM, as was seen in the univariate analysis. The profile LOD for “hot plate latency” (in blue) peaks near 57 cM, also similar to the univariate analysis. The pleiotropy trace (in gray) peaks near 55 cM.

The likelihood ratio test statistic for the test of pleiotropy was 1.2. Based on a parametric bootstrap with 1,000 bootstrap replicates, the estimated p-value was 0.11, indicating weak evidence for distinct QTL for the two traits.

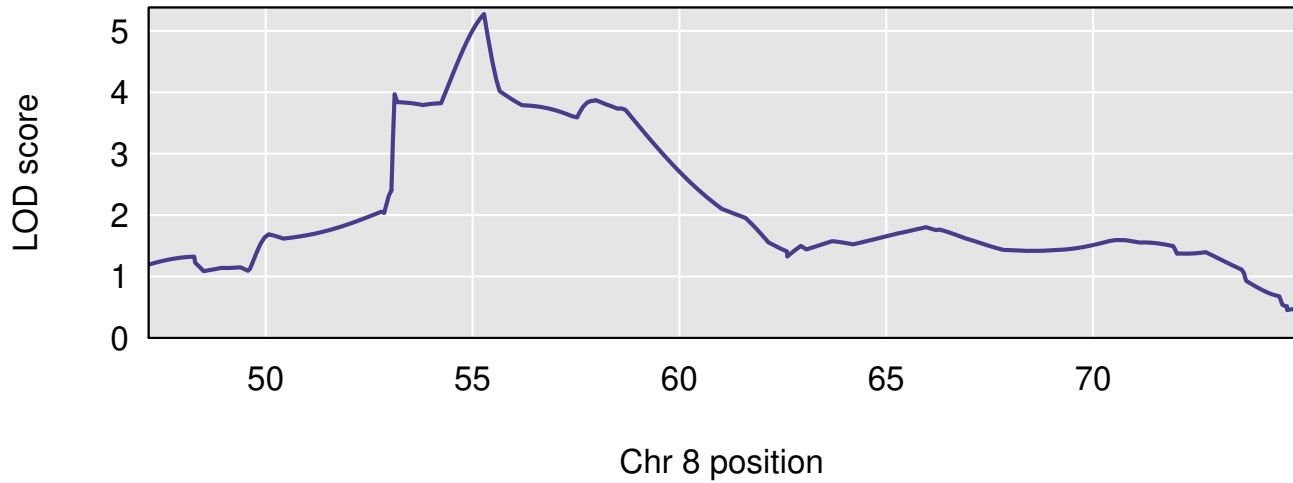

## Discussion

We developed a test of pleiotropy vs. separate QTL for multiparental populations, extending the work of [Jiang and Zeng \(1995\)](#) for multiple alleles and with a linear mixed models to account for population structure. Our simulation studies indicate that the test has power to detect presence of separate loci, especially when univariate trait associations are strong (Figure 1). Type I error rates indicate that our test is slightly conservative (Table 1).

In the application of our method to two behavioral phenotypes in a study of 261 Diversity Outbred mice ([Recla et al. 2014](#); [Logan et al. 2013](#)), we obtained weak evidence ( $p=0.11$ ) for the presence of two distinct QTL, with one QTL (which contained the *Hydin* gene) affecting only “hot plate latency” and a second QTL affecting “percent time in light” (Figure 4).

Founder allele effects plots provide further evidence for the presence of two distinct loci. As [Macdonald and Long \(2007\)](#) and [King et al. \(2012\)](#) have demonstrated in their analyses of multiparental *Drosophila* populations, a biallelic pleiotropic QTL would result in allele effects plots that have similar patterns. While we don’t know that “percent time in light” and “hot plate latency” arise from biallelic QTL, the dramatic differences that we observe in allele effects patterns further support the argument for two distinct loci, with *Hydin* affecting only “hot plate latency”.

### Chromosome 8 LOD for percent time in light

### Chromosome 8 LOD for hot plate latency

**Figure 2** Chromosome 8 univariate LOD scores for percent time in light and hot plate latency reveal broad, overlapping peaks between 53 cM and 64 cM. The peak for percent time in light spans the region from approximately 53 cM to 60 cM, with a maximum near 55 cM. The peak for hot plate latency begins near 56 cM and ends about 64 cM.

### Allele effects for percent time in light

### Allele effects for hot plate latency

**Figure 3** Chromosome 8 univariate LOD scores for percent time in light and hot plate latency reveal broad, overlapping peaks between 53 cM and 64 cM. The peak for percent time in light spans the region from approximately 53 cM to 60 cM, with a maximum near 55 cM. The peak for hot plate latency begins near 56 cM and ends about 64 cM.

Chromosome 8 profile LOD for percent time in light and hot plate latency

**Figure 4** Profile LOD curves for the pleiotropy vs. separate QTL hypothesis test for “percent time in light” and “hot plate latency”. Gray trace denotes pleiotropy LOD values. Triangles denote the univariate LOD maxima, while diamonds denote the profile LOD maxima. For “percent time in light”, the brown triangle obscures the smaller brown diamond. Likelihood ratio test statistic value corresponds to the height of the blue and brown traces at their maxima.

We have implemented our methods in an R package `qt12pleio`, but analyses can be computationally intensive and time consuming. `qt12pleio` is written mostly in R, and so we could likely obtain improved computational speed by porting parts of the calculations to a compiled language such as C or C++. To accelerate our multi-dimensional QTL scans, we have integrated C++ code into `qt12pleio`, using the Rcpp package (Eddelbuettel *et al.* 2011).

Another computational bottleneck is the estimation of the variance components  $V_g$  and  $V_e$ . In future research, we hope to extend our work for the joint analysis of more than two traits, and we will consider other strategies for variance component estimation, including that described by Meyer *et al.* (2018), who implement a bootstrap strategy to estimate variance components for lower-dimensional phenotypes before combining bootstrap variance component estimates into valid covariance matrices for the full multivariate phenotype.

We view tests of pleiotropy as complementary to the sorts of mediation tests and related methods that have become popular for inferring biomolecular causal relationships (Chick *et al.* 2016; Schadt *et al.* 2005; Baron and Kenny 1986). A mediation test proceeds by including a putative mediator as a covariate in the regression analysis of phenotype and QTL genotype; one looks for a substantial reduction in the association between genotype and phenotype. Mediation and pleiotropy tests have different goals: mediation analysis seeks to establish causal relationships, while pleiotropy tests examine whether two traits share a QTL.

Schadt *et al.* (2005) argued that both pleiotropy tests and causal inference methods, such as mediation tests, may contribute to gene network reconstruction. They developed a model selection strategy, based on the Akaike Information Criterion (Akaike 1974), to determine which causal model is most compatible with the observed data. Schadt *et al.* (2005) extended the methods of Jiang and Zeng (1995) to consider more complicated alternative hypotheses, such as the possibility of two QTL, one of which associates with both traits, and one of which associates with only one trait. As envisioned by Schadt *et al.* (2005), we foresee complementary roles emerging for our pleiotropy test and mediation tests in the dissection of complex trait genetic architecture.

Technological advances in mass spectrometry and RNA sequencing have enabled the acquisition of high-dimensional biomolecular phenotypes (Ozsolak and Milos 2011; Han *et al.* 2012). Multiparental populations in *Arabidopsis*, maize, wheat, oil palm, rice, *Drosophila*, yeast, and other organisms enable high-precision QTL mapping (Yu *et al.* 2008; Tisné *et al.* 2017; Stanley *et al.* 2017; Raghavan *et al.* 2017; Mackay *et al.* 2012; Kover *et al.* 2009; Cubillos *et al.* 2013). The need to analyze high-dimensional phenotypes in multiparental populations compels the scientific community to develop tools to study genotype-phenotype relationships and complex trait architecture. Our test, and its future extensions, will contribute to these ongoing efforts.

## Acknowledgments

The authors thank Lindsay Traeger, Julia Kemis, and Rene Welch for valuable suggestions to improve the manuscript. This work was supported in part by National Institutes of Health grant R01GM070683 (to K.W.B.). The research made use of compute resources and assistance of the UW-Madison Center For High Throughput Computing (CHTC) in the Department of Computer Sciences at UW-Madison, which is supported by the Advanced Computing Initiative, the Wisconsin Alumni Research Foundation, the Wisconsin Institutes for Discovery, and the National Science Foundation, and is an active member of the Open Science Grid, which is supported by the National Science Foundation and the U.S. Department of Energy's Office of Science.

**Table S1** Eight founder lines and their one-letter abbreviations.

Founder allele	One-letter abbreviation
A/J	A
C57BL/6J	B
129S1/SvImJ	C
NOD/ShiLtJ	D
NZO/H1LTJ	E
Cast/EiJ	F
PWK/PhJ	G
WSB/EiJ	H

**Table S2** Both “hot plate latency” and “percent time in light” demonstrate multiple QTL peaks with LOD scores above 5.

phenotype	chr	pos	LOD score
percent time in light	8	55.28	5.27
hot plate latency	8	57.77	6.22
percent time in light	9	36.70	5.42
hot plate latency	9	46.85	5.22
percent time in light	11	63.39	6.46
hot plate latency	12	43.52	5.13
percent time in light	15	15.24	5.67
hot plate latency	19	47.80	5.48

Scatterplot of hot plate latency vs. percent time in light

**Figure S1** Scatter plot of “hot plate latency” against “percent time in light”, after applying logarithm transformations and winsorizing both traits.

### Genome-wide LOD for percent time in light

**Figure S2** Genome-wide QTL scan for percent time in light reveals multiple QTL, including one on Chromosome 8.

### Genome-wide LOD for hot plate latency

**Figure S3** Genome-wide QTL scan for hot plate latency reveals multiple QTL, including a peak on Chromosome 8.
